Background	A 62-year-old man sustained blunt thoracic trauma with several rib fractures and aortic injury requiring emergent endovascular aortic stent placement.
Summary	The patient acutely decompensated three days after sustaining blunt thoracic trauma resulting in rib fractures and an aortic injury repaired by an endovascular stent. He suffered a delayed massive hemothorax causing tension physiology and severe hypotension, with immediate tube thoracostomy evacuating 1400 ml of blood. A computed tomography angiogram demonstrated an intact aortic stent but active bleeding from an intercostal artery lacerated by a fragment of a lower rib fracture. He was taken to angiography with no obvious bleeding source identified. He subsequently complained of bilateral lower extremity paraplegia. The patient was found to have an anterior spinal cord infarct, likely due to hypotension in the setting of occlusion of the artery of Adamkiewicz by the endovascular stent.
Conclusion	Delayed massive hemothorax is an extremely rare clinical entity. When it occurred in a patient with a recent endovascular stent for aortic injury, the concomitant hypotension caused infarction of the anterior thoracic spinal cord resulting in paraplegia.
Key Words	hemothorax; tension physiology; endovascular repair of the aorta; paraplegia; blunt thoracic trauma

Case Description

A 62-year-old man with no significant medical or surgical history was brought to the emergency department after a skiing accident. Per a report by prehospital personnel, he had been skiing with his family when he lost control and struck a tree back-first. He wore a helmet, denied head strike, had no loss of consciousness and denied using any anticoagulant medication. On his arrival, he was hemodynamically stable, alert, and oriented, complaining of midline thoracic and lumbar back pain as well as left shoulder pain. He was neurologically intact and otherwise exhibited a normal physical exam. His laboratory values were significant only for a leukocytosis of 19.9 *103/μL, an elevated creatinine of 1.29 mg/dL, and a mild lactatemia of 1.5 mmol/L.

Computed tomography (CT) scans of his head and cervical spine revealed no abnormalities. A CT scan with intravenous contrast of his chest, abdomen, and pelvis demonstrated bilateral trace hemothoraces, a small left pneumothorax, minimally displaced fractures of the left lateral 7 to 11 ribs and right lateral 11 to 12 ribs, grade I splenic laceration, fracture of the superior fragment of T12 vertebral body with mild anterior displacement, and a focal dissection of the aorta at T11 with moderate surrounding hematoma without active extravasation of contrast. Due to the small size of the left pneumothorax and absence of respiratory symptoms or hypoxia, a decision was made not to place a tube thoracostomy.

The patient was taken for emergent percutaneous endovascular stenting of his thoracic aortic injury. A 20 cm supraceliac endograft was placed over the area of aortic dissection without difficulty. He tolerated the procedure well and was taken to the intensive care unit in stable condition. Subsequently, he had several uneventful hospital days, with the resumption of a regular diet, removal of his central line and urinary catheter, and mobilization out of bed while wearing a back brace.

In the early morning hours of postoperative day 3, he complained of increasing left chest pain and received oral analgesics. He had an increasing sinus tachycardia from 77 bpm to 110 bpm. Several minutes after going to the bedside commode, he had a pre-syncopal episode and was helped back to his bed. He subsequently lost consciousness; immediate vital signs demonstrated a systolic blood pressure of 60 mmHg and a heart rate of 55 bpm. His skin was ashen and diaphoretic. He was given epinephrine with an improvement of his hemodynamics, and he regained consciousness. He immediately complained of bilateral leg paralysis. Anesthesia was called for emergent intubation. He was given a 1 L crystalloid bolus, received 200 μg of phenylephrine, and started on a phenylephrine drip, rapidly titrated to 150 mcg/hour. An electrocardiogram demonstrated sinus tachycardia, labs were unremarkable, and a chest radiograph revealed a large left pleural effusion with a rightward displacement of his mediastinum and trachea (Figure 1). A tube thoracostomy was inserted into his left chest, immediately evacuating approximately 1400 ml of frank blood. His hemodynamic instability resolved within minutes. Aggressive balanced blood product resuscitation was initiated.

He was taken for a CT angiogram, which demonstrated an intact vascular stent, but a left hemothorax with active extravasation from a lacerated left intercostal artery at approximately the ninth rib (Figure 2).

Thus, the patient was taken to the interventional radiology suite for angiography. However, the intercostal artery suspected of bleeding was unable to be opacified due to coverage by the endovascular aortic stent. An attempt was made to enter the internal thoracic artery, which inconstantly provides collateral flow to the intercostal arteries, but this was unable to be opacified. The thoracodorsal artery was cannulated, which appeared to have some small collateralization with the intercostal system, and a segment was selectively embolized using Gelfoam.

The patient was returned to the intensive care unit. The chest tube output began to decrease in hourly output. The patient continued to require peripheral vasopressor support to maintain adequate blood pressure. Vascular surgery was consulted regarding the complaints of paraplegia and recommended liberal blood transfusions to maintain a hemoglobin of at least 9 g/dL and norepinephrine to maintain a mean arterial pressure of at least 90 mmHg. After consultation with neurosurgery, placement of a spinal drain to improve spinal perfusion pressure was considered but ultimately was decided against due to his improving exam.

On post-procedure day one, the patient continued to demonstrate three out of five strengths in bilateral lower extremities, with preserved sensation. On post-procedure day two, the patient was extubated, and the vasopressors were weaned off. An MRI of the lumbar spine demonstrated an anterior spinal cord infarct spanning T9 to L1, as well as an epidural hematoma at the T11/T12 levels and demonstration of the T12 vertebral body fracture (Figure 3). Spine surgery was consulted, who recommended continued conservative management. On post-procedure day five, the patient was transferred from the intensive care unit to a spine floor. He demonstrated neurogenic bowel and bladder dysfunction, requiring intermittent urinary catheterizations and daily suppositories and rectal stimulation.

Additionally, his chest tube clotted, requiring placement of a small anterior pigtail tube to evacuate a residual pneumothorax. Both tubes were pulled without complications in subsequent days. He continued intensive physical therapy, and on hospital day 18, he was able to stand from the bed using a walker. He was discharged to an acute rehabilitation facility with his lumbar back brace and a urinary catheter in place. He has not been seen in follow-up due to his out-of-state residency.

Discussion

The case describes a trauma patient who experienced two distinct, rare clinical complications: delayed massive hemothorax with tension physiology and paraplegia complicating endovascular aortic repair.

Upon review, there were several opportunities for improved clinical decision-making. First, the standard of care for massive hemothorax is operative control of bleeding and not angioembolization. This conclusion is especially true with any history of aortic stenting, which may prohibit cannulization of the bleeding intercostal artery. Nonetheless, a discussion between the trauma surgery and interventional radiology teams yielded a decision to attempt endovascular control of bleeding before proceeding to the operating room. Although no definite bleeding source was identified on angiography, the chest tube output diminished significantly after adequate resuscitation with blood products, and any operative exploration was ultimately aborted.

Second, massive transfusion protocol should have been initiated earlier. After hemodynamic instability with an identified source of ongoing bleeding, earlier rapid transfusion may have helped maintain perfusion of the spinal cord.

Delayed hemothorax is an underappreciated and relatively common complication after blunt thoracic trauma. In one study of 1,382 patients sustaining any type of chest trauma, radiographically apparent effusions were observed in 11% at 14 days.[1] In comparison, pneumonia complicated only 2% of patients sustaining chest trauma. Of the patients with pleural effusions, only 50% complained of chest pain and only 22% of dyspnea. However, only 3% required drainage, equal to 0.36% of the total study population. Age greater than or equal to 70 years conferred the highest relative risk of developing delayed hemothorax, followed by the presence of high or midrib fracture, age 45–70 years, and presence of at least three rib fractures (specificity 90.7%, sensitivity 33.9%, receiver operator curve 0.78). Another study found that 92% of cases of delayed hemothorax were preceded by some clinically apparent symptom, commonly dyspnea, chest pain, coughing, or diaphoresis.[2] The time delay from initial injury to hemothorax can vary significantly; one study found that identification of new pleural effusion occurred anywhere from 18 hours to 11 days after traumatic injury.[3] Rib fractures on initial presentation post-thoracic injury should increase suspicion of the possibility of developing a hemothorax later in the course of care. Any number of rib fractures has been associated with a higher risk of delayed bleeding into the pleural space. The cause of bleeding is most commonly laceration of the diaphragm, intercostal artery, and/or phrenic artery.[3–6]

Massive hemothorax, generally defined as the evacuation of more than 1500 ml of blood immediately after tube thoracostomy or 200 ml/hr of output for four hours, is an infrequent complication of blunt thoracic trauma. Massive hemothorax requires surgical intervention to identify and stop the source of bleeding.

Delayed massive hemothorax after a blunt thoracic injury is an extremely rare entity. In a single-institution study of 1278 patients sustaining blunt thoracic trauma, only five (0.4%) had delayed massive hemothorax. All underwent emergent thoracotomy and were found to be bleeding from a laceration of the diaphragm by a sharp fragment from a nearby rib fracture.

Any patient with blunt thoracic trauma experiencing new symptoms after their initial presentation should be evaluated with a chest radiograph. Early recognition of and intervention for massive hemothorax cannot be understated due to the risk of significant morbidity or mortality. Untreated, retained hemothorax may lead to complications such as empyema and fibrothorax and more extended hospital stays.[1] Therefore, continuous evaluation for hemothorax, especially with potentially delayed presentation, can facilitate its identification and resolution and confer a more favorable prognosis with timely tube thoracostomy and adequate resuscitation.[3] If there is aortic damage requiring thoracic endovascular aortic repair (EVAR), the obstructing endovascular stent-grafts may render lacerated intercostal arteries unable to be opacified or embolized via angiography, preventing control of the bleeding.

Traumatic thoracic aortic injury can be immediately life-threatening and can lead to aortic dissection, rupture, or thrombus, and warrants prompt surgical intervention. Compared to open surgical repair, EVAR has been shown

to confer significantly lower mortality and risk of delayed postoperative paraplegia, one of the most commonly recognized complications of thoracic aortic aneurysm repair.[7] However, the risk of paraplegia after EVAR is not insignificant, with a reported incidence from 0.21 to 15%.[7–11] Cheung et al.[12] also found a considerable variation in the timing of delayed-onset paraplegia, with the initial episode occurring 6.4 to 110 hours after surgery and a second episode occurring an average of 176 hours postoperatively. Another study by Maniar et al.[10] reported delayed paraplegia occurring up to 27 days after EVAR, with most cases associated with a documented episode of hypotension.

Lower extremity paraparesis and paraplegia result from spinal cord ischemia (SCI). The incidence of SCI is much greater for endovascular repair of the thoracic aorta, which can be as high as 12% compared to the abdominal aorta. SCI has been independently associated with preoperative renal insufficiency.[13,14] Other contributing factors to the development of SCI include perioperative hypotension, increased cerebrospinal fluid (CSF) pressure, and occlusion of supplying arteries, such as the artery of Adamkiewicz or intercostal arteries by stent-grafts.[10,12]

Damage to or occlusion of the artery of Adamkiewicz, a posterior intercostal artery branch, can rarely result in anterior cord syndrome. This artery is the most prominent thoracic radicular artery. It can be found between the T9 and T12 levels in most individuals, supplying the lower, anterior two-thirds of the spinal cord via the anterior spinal artery. This territory supplied by the anterior spinal artery is the most common location of SCI because of its single blood supply, unlike the dual supply from the two posterior spinal arteries that feed the posterior spinal cord. Spinal cord infarction is also most common at the lower thoracic and upper lumbar levels, manifesting as complete lower extremity motor paralysis and loss of temperature and pain perception distal to the lesion, as well as urinary and rectal incontinence or retention. Since the posterior columns are spared, light touch, vibration, and proprioception are preserved.[15,16]

Patients with delayed-onset paraplegia have been found to have an increased chance of recovery compared to those in whom paraplegia was diagnosed upon emergence from anesthesia, and most patients with delayed-onset paraplegia experience full neurologic recovery.[12,14] Despite the possible reversibility of this complication, watchful postoperative monitoring is imperative in all patients who have undergone EVAR. Avoiding even transient hypotension with blood pressure augmentation to higher mean arterial pressures and decreasing CSF pressures have been shown to reduce the risk of paraplegia.[10,14] Decreasing CSF pressure using spinal drains has also been demonstrated to protect against spinal cord ischemia during EVAR.[17]

Conclusion

Delayed massive hemothorax is an extremely rare clinical entity. When it occurred in a patient with a recent endovascular stent for aortic injury, the concomitant hypotension caused infarction of the anterior thoracic spinal cord resulting in paraplegia.

Lessons Learned

Delayed massive hemothorax is a rare but highly morbid complication of blunt thoracic trauma, and any new complaint should be thoroughly investigated with chest radiography. Paraplegia is a rare but highly morbid complication following thoracic endovascular repair, and every effort should be made to avoid postoperative hypotension
